Background: Curcumin is traditionally used as an herbal medicine. We explored the efficacy of intrathecal curcumin in relieving both postoperative and inflammatory pain and elucidated the mechanisms of action of curcumin interacting with γ-aminobutyric acid (GABA) and opioid receptors at the spinal level.

Methods: Experimental pain was induced in male Sprague-Dawley rats via paw incision or injection of intraplantar carrageenan. After examination of the effects of intrathecal curcumin on the pain, GABA and opioid receptor antagonists were intrathecally administered to explore the involvement of GABA or opioid receptors on the effect of curcumin. Additionally, the expression levels of the GABA and opioid receptors were assessed.

Results: Intrathecal curcumin reduced the withdrawal threshold of both incisional surgery- and carrageenan injection-induced nociception. Intrathecal GABA and opioid receptor antagonists reversed the curcumin-mediated antinociception. Incisional surgery decreased the levels of the GABA receptors mRNA, but little changed the levels of the opioid receptors mRNA. Carrageenan injection increased the levels of the opioid receptors mRNA, but not the GABA receptors mRNA levels. Intrathecal curcumin increased or decreased the levels of GABA receptors mRNA and opioid receptors mRNA in the spinal cords of incised or carrageenan-injected rats, respectively.

Conclusions: Intrathecal curcumin was effective to postoperative and inflammatory pain and such antinociception of curcumin was antagonized by both GABA and opioid receptor antagonists. Also, intrathecal curcumin altered the levels of GABA and opioid receptors. Thus, spinal GABA and opioid receptors may, respectively, be directly or indirectly involved when curcumin alleviates postoperative and inflammatory pain.

Key Words: Curcumin, γ-aminobutyric acid and opioid receptor, Postoperative and inflammatory pain, Spinal cord.
both drugs cause serious side-effects including respiratory depression, gastrointestinal discomfort, renal dysfunction, and hematologic abnormality. Furthermore, and unfortunately, tissue injury may unexpectedly enhance the activation of peripheral nociceptors, causing an activity-dependent increase in central neuronal excitability, in turn inducing both peripheral and central sensitization [1,2]. Such changes contribute to post-injury hypersensitivity, which manifests as an increase in responsiveness to painful stimuli (hyperalgesia), and a decrease in the pain threshold rendering (usually) non-painful stimuli painful (alldynia). Such events are not easy to manage using common analgesics, and compromise quality-of-life. Therefore, active pain therapy should commence early to avoid such sensitization. However, when pain develops, endogenous protective systems become activated to counteract the pain. Both γ-aminobutyric acid (GABA) and opioid receptors are well-known endogenous systems modulating nociception in the spinal cord [3].

Recently, much effort has been devoted toward development of materials meeting unmet therapeutic needs. In this context, traditional medicines have attracted a great deal of attention.

Curcumin is the principal biologically active component of turmeric, which is widely used as a food-coloring agent. Interestingly, curcumin has long been employed as an herbal medicine in Asian countries, including Korea. It is known that curcumin exhibits a variety of medical effects including anti-inflammatory action [4]. Recently, it has been shown that curcumin attenuates nociceptive behavior at the spinal level [5,6]. However, the spinal mechanisms of action of curcumin have not been fully elucidated.

Thus, the purposes of the present study were to explore spinal GABA and opioid receptor expression patterns in rats in which postoperative and inflammatory pain had been induced; to examine the effects of intrathecal curcumin on both types of pain; and, further, to assess the effects of curcumin on GABA and opioid receptor levels in the spine.

**MATERIALS AND METHODS**

**Animal preparation**

All experimental protocols were reviewed and approved by the Institutional Animal Care and Use Committee of Chonnam National University (no. CNU IACUC-H-2010-8). Adult male Sprague-Dawley rats (250–300 g) were used in the present study. Animals were housed four to a cage and kept in a vivarium maintained at 22°C with a 12 hours : 12 hours alternating light/dark cycle. All rats received food and water *ad libitum*. All test drugs were intrathecally administered. Thus, rats were implanted with intrathecal catheters under sevoflurane anesthesia, as described previously [7]. An 8.5-cm-long polyethylene-10 catheter was advanced caudally, through an incision in the cisternal membrane, to the thoracolumbar level of the spinal cord. The exterior portion of the catheter was secured at the skull via subcutaneous tunneling, and was closed with a 30-gauge wire. The skin was sutured with 3-0 silk. After catheter implantation, rats were housed in individual cages. Only animals with no evidence of neurological deficits developing after catheter implantation were included in the present study; such rats were housed individually. The behavioral study was performed 5 days after intrathecal catheterization.

**Drugs**

The following drugs were used in the present study: curcumin [1,7-Bis (4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione, Tocris Cookson, UK]; bicuculline [R-(R*,S*)]-6-(5,6,7,8-Tetrahydro-6-methyl-1,3-dioxolo[4,5-g]isoquinolin-5-yl) furo[3,4-e]-1,3-benzodioxol-8 (6H)-one, Tocris Cookson, UK]; saclofen [(3S,5S)-5-Amino-2-(4-chlorophenyl) propylsulfonic acid; Tocris Cookson, UK]; CTOP [D-Phe-Cys-Tyr-D-Trp-Orn-Yhr-NH$_2$, Tocris Cookson, UK]; naltrindole [17-(Cyclopropylmethyl)-6,7-dehydro-4,5-epoxy-3,14-dihydroxy-6,7-2’,3’-indolomorphinan hydrochloride, Tocris Cookson, UK]; and GNTI [5’-Guadinidinyl-17-(cyclopropylmethyl)-6,7-dehydro-4,5-epoxy-3,14-dihydroxy-6,7-2’,3’-indolomorphinan dihydrochloride, Tocris Cookson, UK]. Curcumin was dissolved in 10% dimethylsulfoxide (DMSO), whereas all other drugs were dissolved in distilled water. Intrathecal administration of all agents was performed using a hand-driven, gear-operated syringe pump. All drugs were delivered in volumes of 10 µl followed by an additional 10 µl of normal saline to flush the catheter [8].
Nociceptive test

Postoperative pain model

Postoperative pain was induced during sevoflurane anesthesia, as previously described [9]. The plantar surface of the left hindpaw was rendered sterile. A 1-cm longitudinal incision was made through the skin and fascia of the plantar aspect of the foot, commencing 0.5 cm from the proximal edge of the heel and extending toward the toes. The plantaris muscle was elevated and incised longitudinally, leaving the muscle origin and insertional points intact. After hemostasis was achieved by application of gentle pressure, two 4-0 silk sutures were placed in a mattress fashion along the wound. Antibiotic ointment was next applied to the incision site and rats were allowed to recover in their cages. Wounds were checked prior to behavioral testing.

Inflammatory pain model

Inflammatory pain was induced by intraplantar injection of carrageenan [10]. Animals were injected subcutaneously with 100 \( \mu \)l amounts of 2\% (w/v) carrageenan (degraded \( \lambda \)-carrageenan, Sigma Aldrich, USA) into the center of the plantar surface of the left hind paw, using a 30-G needle. Carrageenan was dissolved in saline to form the 2\% (w/v) solution and stored at room temperature for 24 hours before use. Carrageenan was injected under sevoflurane anesthesia.

Behavioral pain testing

The extent of pain was evaluated by measurement of the paw withdrawal threshold to mechanical stimulation delivered using von Frey filaments. Withdrawal thresholds were measured prior to manipulation, on rats in cages with wire mesh floors, and these measurements were the baseline values. Next, operations were performed or carrageenan injected, and withdrawal thresholds measured for 4 hours. Paw withdrawal thresholds in response to mechanical stimulation were measured using the up-and-down method [11]. Employing calibrated von Frey filaments (Stoelting, USA) inserted from underneath each cage, through openings in the wire mesh floor, to touch the hindpaw. A series of eight von Frey filaments (0.4, 0.7, 1.2, 2.0, 3.6, 5.5, 8.5, and 15 g) were applied vertically to the plantar surface of the hindpaw for 5 seconds, with sufficient force to bend the filament. Brisk withdrawal or paw flinching was considered to be a positive response. In the absence of a response to the 15 g filament, a 15 g cutoff value was assigned. All tests were performed in duplicate, with approximately 3 minutes between each test, and average values were used. Only rats exhibiting marked allodynia (a withdrawal threshold < 5 g) after paw incision were studied. At the end of the experiment, all rats were euthanized using volatile anesthetics.

Experimental protocol

On the days of behavioral experiments, rats were placed in wire cages for 30 minutes to allow acclimation, and were next allocated to receive an experimental drug. The same volume of vehicle (distilled water or DMSO) was given to control animals. All rats were used only once (i.e., no rat received two test agents). All experimental tests were conducted by investigators blinded to treatment.

Effects of curcumin on postoperative and inflammatory pain

Withdrawal thresholds were determined before and 2 hours after incision, and before and 4 hours after carrageenan injection, and after intrathecal administration of curcumin (10, 30, or 100 \( \mu \)g in rats subjected to incisional pain; and 30, 100, or 300 \( \mu \)g in animals subjected to inflammatory pain). Withdrawal thresholds measured 2 hours after incision or 4 hours after carrageenan injection were considered to reflect the post-incision/post-injection control thresholds. Test drugs were intrathecally delivered immediately after measurement of these thresholds. Each ED\(_{50}\) value (the dose producing a 50\% reduction in the control response) of curcumin was calculated separately.

GABA and opioid receptor expression upon induction of postoperative and inflammatory pain

The levels of mRNAs encoding GABA (A and B) and opioid receptors (\( \mu \), \( \delta \), and \( \kappa \)) were measured in the left dorsal quadrant of the spinal cord in naïve, incised carrageenan-injected and curcumin-treated rats (n = 16) via reverse tran-
Curcumin was administered intrathecally 2 or 4 hours after incision or carrageenan injection, respectively. At 2 hours after incision, 4 hours after carrageenan injection, and 60 minutes after curcumin administration, rats were euthanized by decapitation and the spinal cords quickly removed and stored at −80°C. The regions of spinal cords from L4 to L6 were dissected out and total RNA extracted using an RNAiso Plus kit (Takara Bio, Japan) according to the manufacturer’s instructions; precipitated with isopropanol; washed with 75% (v/v) EtOH; air-dried; and dissolved in 20-μl amounts of diethyl pyrocarbonate-treated water. RNA yields were determined by measuring absorbances at 260 and 280 nm. RT-PCR was performed with the aid of a PrimeScript™ RT-PCR kit (Takara Bio, Japan) according to the manufacturer’s protocol. Total RNA (1 μg amounts) was reverse-transcribed for 60 minutes at 42°C. PCR amplification was performed with the aid of an HS Prime Taq Premix kit (Genet Bio, Korea), and featured 30 cycles of denaturation (95°C for 30 seconds), annealing (57°C for 30 seconds), and extension (72°C for 30 seconds). Primer sequences amplifying the GABA receptors (A and B), the opioid receptors (μ, δ, and κ), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH), were as follows: GABA-A, forward 5'-AAG CTA TGG ACA GCC CT-3' and reverse 5'-CCT CTG TGA TAC GCA GGA GTT-3' (380 bp); GABA-B, forward 5'-ATG TAC CGT GCC TTG AC-3' and reverse 5'-TCG TCA AGG TAC CGT GGC TTG AC-3' (490 bp); GABA receptor antagonist (bicuculline, 0.3 mg, n = 11); a GABA receptor antagonist (saclofen, 100 μg). The opioid receptor antagonists used were as follows: a μ opioid receptor antagonist (CTOP, 15 μg, n = 11); a δ opioid receptor antagonist (naltrindole, 10 μg, n = 11); and a κ opioid receptor antagonist (GNTI, 50 μg, n = 10). The antagonists were given intrathecally 10 minutes before administration of intrathecal curcumin (100 or 300 μg) and behavioral tests were performed after curcumin delivery. The maximal doses of GABA or opioid receptor antagonists that did not affect control responses, or cause behavioral abnormalities, were determined in pilot experiments or calculated by reference to earlier data [12]. The GABA receptor antagonists used were as follows: a GABA-A receptor antagonist (bicuculline, 0.3 μg); and a GABA-B receptor antagonist (saclofen, 100 μg). The opioid receptor antagonists used were as follows: a μ opioid receptor antagonist (CTOP, 15 μg, n = 11); a δ opioid receptor antagonist (naltrindole, 10 μg, n = 11); and a κ opioid receptor antagonist (GNTI, 50 μg, n = 10). The antagonists were given 2 or 4 hours after incision and carrageenan injection, respectively (as described in Results). To examine behavioral changes induced by curcumin, high drug doses (300 μg) were given intrathecally to five additional rats. Motor function was assessed by evaluation of the placing-stepping and righting reflexes. The first reflex was evoked by drawing the dorsum of each hind paw across the edge of a table. Healthy rats generally try to place the paw ahead, into a position facilitating walking. The second reflex was evaluated by placing each rat horizontally with its back on the table. Healthy rats exhibit immediate and co-ordinated bodily twisting to assume the upright position. Pinna and corneal reflexes were evaluated using a paper string [13].
Each reflex was evoked by stimulation of the ear canal or the cornea with a string. Healthy rats spontaneously shake their heads or blink, respectively. Behavioral normality was scored as present or absent.

**Statistical analysis**

Data are expressed as means ± standard errors of the means. Time response data are presented as withdrawal thresholds. Dose-response data are presented as percentages of the maximum possible effect (%MPE). To calculate ED\textsubscript{50} values of curcumin given to alleviate incisional and inflammatory pain, the withdrawal threshold data derived via von Frey filament testing were converted to %MPEs, using the formula: %MPE = ([post-drug threshold − baseline post-incision threshold] / [pre-incision threshold − baseline post-incision threshold]) × 100 for postoperative pain; and %MPE = ([post-drug threshold − baseline post-injection threshold] / [pre-injection threshold − baseline post-injection thresh-

**Fig. 2.** Expression levels of mRNAs encoding γ-aminobutyric acid (GABA) and opioid receptors in the left dorsal horn of the spinal cord in naïve, incised, and carrageenan-injected rats. Data are presented as relative values of GABA and opioid receptors to that of glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Each bar represents the mean ± SEM of data from four rats. Reverse transcriptase polymerase chain reaction detected mRNA bands corresponding to the GABA and opioid receptors in naïve animals. (A) Quantitative analysis indicated that incisional surgery reduced the levels of expression of mRNAs encoding GABA receptors, but not of those encoding opioid receptors. (B) Carrageenan injection increased expression of opioid receptor mRNAs, but not those of GABA receptor mRNAs. *P < 0.05, †P < 0.01, ‡P < 0.001 compared to naïve rats.
old]) × 100 for inflammatory pain. Dose-response data were analyzed by one-way analysis of variance with Scheffe post hoc testing. ED₅₀ values with 95% confidence intervals (CIs) were calculated via linear regression. The pharmacological actions of curcumin, and RT-PCR data, were compared using the t-test. P values < 0.05 were considered to reflect statistical significance.

**RESULTS**

Incisional surgery and carrageenan injection decreased withdrawal thresholds, and such effects persisted for approximately 4 days in the ipsilateral paw, whereas the two nociceptive stimuli per se did not affect withdrawal thresholds of the contralateral normal hindpaw (Fig. 1). The decreases in withdrawal thresholds were greatest 2 or 4 hours (P < 0.001 vs. contralateral) after incision and carrageenan injection, respectively (Fig. 1).

RT-PCR revealed that mRNAs encoding opioid receptors (μ, δ, and κ) and GABA receptors (A and B) were present in the naïve rat lumbar spinal cord (Fig. 2). After incisional surgery, the levels of mRNAs encoding both GABA-A (P < 0.05 vs. naïve) and GABA-B (P < 0.001 vs. naïve) receptors decreased, but the levels encoding opioid receptors remained unchanged, compared to naïve rats (Fig. 2A). After carrageenan injection, the levels of mRNAs encoding all three μ (P < 0.05 vs. naïve), δ (P < 0.01 vs. naïve), and κ (P < 0.05 vs. naïve) subtypes of spinal opioid receptors increased, whereas the levels encoding the GABA receptors levels remained unchanged, compared to naïve rats (P > 0.05 vs. naïve, Fig. 2B).

Intrathecal curcumin dose-dependently increased the
withdrawal thresholds of incised (P < 0.01 at 100 µg vs. vehicle) and carrageenan-injected (P < 0.05 at the 300 µg vs. vehicle) paws (Figs. 3 and 4). The ED₅₀ values (with 95% CIs) of curcumin used to alleviate postoperative and inflammatory pain were 22.3 µg (12.2–40.8 µg) and 126.5 µg (59.6–268.6 µg), respectively.

The antinociceptive effect of intrathecal curcumin on postoperative pain induced by incisional surgery was antagonized by intrathecal bicuculline (a GABA-A receptor antagonist, P < 0.01 vs. curcumin) and saclafen (a GABA-B receptor antagonist, P < 0.001 vs. curcumin) (Fig. 5A). Additionally, intrathecal curcumin administration increased the levels of mRNAs encoding both GABA-A (P < 0.01 vs. incised) and GABA-B (P...
Intrathecal CTOP (a \( \mu \) opioid receptor antagonist, \( P < 0.001 \) vs. incised) receptors in the spines of incised rats (Fig. 5B). Intrathecal CTOP, naltrindole (a \( \delta \) opioid receptor antagonist, \( P < 0.001 \) vs. curcumin), and GNTI (a \( \kappa \) opioid receptor antagonist, \( P < 0.001 \) vs. curcumin) reversed the antinociceptive effect of curcumin on incisional pain (Fig. 6A), but intrathecal curcumin did not affect the levels of spinal cord opioid receptors (Fig. 6B).

The antinociceptive effect of intrathecal curcumin on inflammatory pain induced by carrageenan injection was antagonized by intrathecal CTOP, naltrindole, and GNTI (Fig. 7A). Additionally, intrathecal curcumin decreased the levels of mRNAs encoding the three opioid receptors in the spines of carrageenan-injected rats (Fig. 7B). Intrathecal bicuculline and saclofen reversed the antinociceptive effect of intrathecal curcumin on inflammatory pain (Fig. 8A), but intrathecal curcumin did not affect the levels of mRNAs encoding spinal GABA receptors (\( P > 0.05 \) vs. incised, Fig. 8B).

The placing-stepping reflex, the righting reflex, and the pinna and corneal reflexes were present after intrathecal administration of curcumin at the highest doses used.

**DISCUSSION**

We showed, in the present study, that incisional surgery and carrageenan injection decreased withdrawal thresholds in the ipsilateral, but not contralateral, paws. These findings are consistent with those of previous reports [9,10], validating the postoperative and inflammatory pain models used in the present study. In addition, RT-PCR revealed that both GABA (A and B) and opioid receptors (\( \mu, \delta, \) and \( \kappa \)) were expressed in the spinal cords of naive rats, in line with previous findings [14,15]. Both the GABA and opioid systems are major contributors to nociceptive processing in the spinal cord [4], and we thus focused on these two systems. Several lines of evidence indicate that GABA and opioid receptor agonists exert antinociceptive actions at the spinal level. Intrathecal GABA receptor agonists decreased complete Freund’s adjuvant-induced mechanical hyperalgesia [12], mechanical allodynia in neuropathic pain [16], and incisional pain [17]. Intrathecal opioid receptor agonists also triggered antinociceptive activity in animals subjected to incisional and formalin-induced [13,18]. In the present study, the levels of mRNAs encoding spinal GABA and opioid receptors decreased or increased (respectively) after incisional surgery and carrageenan injection. However, neither incisional surgery nor carrageenan injection materially affected the levels of spinal opioid or GABA receptors. Previous molecular biological studies of incisional and inflammatory pain have yielded a variety of results. The expression levels of spinal cord GABA-A, and opioid \( \mu \) and \( \delta \) receptors, were not affected by incision [17,19]. GABA-B receptor binding was reduced after injection of complete Freund’s adjuvant, whereas that of the GABA-A receptor was unchanged [20]. No changes in the levels of mRNAs encoding the \( \mu, \delta, \) or \( \kappa \) opioid receptors were observed in the spinal cord after injection of formalin [21]. The expression levels of the \( \mu, \delta, \) and \( \kappa \) opioid receptors increased after injection of complete Freund’s adjuvant [22,23]. Such findings suggest that the GABA and opioid receptor systems may be differentially activated depending on the form of nociception required at the spinal level. Our present data allow us to advance certain suggestions. Reduction of GABA receptor expression in rats experiencing postoperative pain suggests that acute pain per se, inflicted (for example) by incisional surgery, may inhibit GABA receptor expression in the spinal cord. Thus, high doses of spinal GABA receptor agonists may be necessary to treat postoperative pain. On the other hand, the increased levels of opioid receptors evident after carrageenan injection suggests that inflammatory pain per se may stimulate spinal cord opioid receptor expression in an effort to reduce pain, and it may thus be possible to relieve pain using small doses of opioids. Interestingly, the spinal cord levels of neither the opioid nor the GABA receptors were altered upon infliction of postoperative or inflammatory pain, suggesting that receptor levels may not be directly affected by pain.

In the present study, intrathecal curcumin exhibited antinociceptive effects on postoperative and inflammatory pain induced by incision and carrageenan injection, respectively. Previous studies have revealed the antinociceptive actions of curcumin. Intrathecal curcumin attenuated formalin-induced nociception, spinal nerve ligation-induced neuropathic pain and complete Freund’s adjuvant-induced pain hypersensitivity, which was mediated through the inhibition of glial activation [5,6,24]. In addition, oral curcumin reduced the formalin-induced flinching response, thermal hyperalgesia and neuropathic pain [25–27]. Intravenous curcumin attenuated visceral nociception [28]. Intraperitoneal curcumin and
a synthetic curcuminoid analog reduced both formalin- and thermally induced nociception and neuropathic pain [29,30]. An interesting finding of the current study was that curcumin action varied depending on the type of nociception analyzed. The ED$_{50}$ for inflammatory pain was five-fold higher than that for postoperative pain, suggesting that curcumin may be considerably more effective when used to treat postoperative rather than inflammatory pain.

In the current study, the antinociceptive effects of intrathecal curcumin on postoperative and inflammatory pain were antagonized by intrathecal GABA (A and B) and opioid (µ, δ, and κ) receptor antagonists. However, the RT-PCR data differed from those of the behavioral study. Intrathecal curcumin elevated the levels of GABA receptors, but not opioid receptor levels, when postoperative pain was induced. In contrast, intrathecal curcumin decreased opioid receptor levels, but not the levels of GABA receptors, when inflammatory pain was inflicted. In addition, we found that incisional surgery affected GABA receptor levels only, and carrageenan injection changed opioid receptor levels only. Together, these findings suggest that postoperative pain may be modulated by spinal cord GABA rather than opioid receptors. Additionally, curcumin may directly affect the synthesis of mRNAs encoding the spinal GABA receptors that mediate antinociception of postoperative pain. Opioid receptors may play indirect roles only in this context, when it is considered that no changes in the expression levels of opioid receptor mRNAs were noted despite the fact that curcumin activity was antagonized by opioid receptor blockers. On the other hand, the roles played by GABA and opioid receptors upon infliction of inflammatory pain may be the opposite of those under conditions of postoperative pain. This is the first work to clarify the pharmacologic mechanisms of curcumin at the spinal level. In general, curcumin may be a useful therapeutic option for management of postoperative and inflammatory pain at the spinal level.
